

## Lecture 22

Play same game as last lecture to calculate ratios of cross sections

$$\sigma = \frac{1}{2E_1} \frac{1}{2E_2} |M|^2 d\Pi_{LIPS}$$

$$\frac{\sigma(ee \rightarrow \text{"jets"})}{\sigma(ee \rightarrow \mu\mu)} = \frac{\sum_{\text{"quarks"}} \sum_{\text{"colors"}} |M(ee \rightarrow qq)|^2}{\underbrace{|M(ee \rightarrow \mu\mu)|^2}_{|M_0|^2}}$$

$$|M(ee \rightarrow qq)|^2 = Q_q^2 |M_0|^2$$

Define,

$$R \equiv \frac{\sigma(ee \rightarrow \text{"jets"})}{\sigma(ee \rightarrow \mu\mu)} = \sum_{\text{quarks}} Q_q^2$$

R is sensitive to the number of quarks.

$R(E_{CM})$  at 4 GeV only u,d,s can contribute.

$$R(E_{CM} < 4 \text{ GeV}) = \sum_{q \in u,d,s} Q_q^2 = \frac{4}{9} + \frac{1}{9} + \frac{1}{9} = \frac{2}{3}$$

$$R(E_{CM} > 4 \text{ GeV}) = \sum_{q \in u,d,s,c} Q_q^2 = \frac{4}{9} + \frac{1}{9} + \frac{1}{9} + \frac{4}{9} = \frac{10}{9}$$

Problem, when you measure R you actually see

Measuring R determines  $N_{\text{quarks}}$  and  $N_{\text{colors}}$ .

Scan  $E_{CM}$  measure R, changes at values of  $m_q$ .

### Discovery of the gluon

Cant produce gluons from e's, but you can radiate them from q's produced in  $ee \rightarrow qq$  collisions. "Mercedes" events smoking gun for gluons.

$$\frac{\sigma(ee \rightarrow 3\text{-jets})}{\sigma(ee \rightarrow 2\text{-jets})} \sim \alpha_s N_{\text{gluons}}$$

Now collider physics in more detail.

Collide protons / Measure how often a certain type of interaction occurs.

(Weve already talked about this...)

$$r_p \sim GeV^{-1} \sim 10^{-15}m$$

$$r_p^2 \sim 10^{-26}cm^2 = 0.01 \underbrace{\text{“barns”}}_{\text{Long story}}$$

barn is about the size of a Uranium atom.

At the LHC, interesting processes are

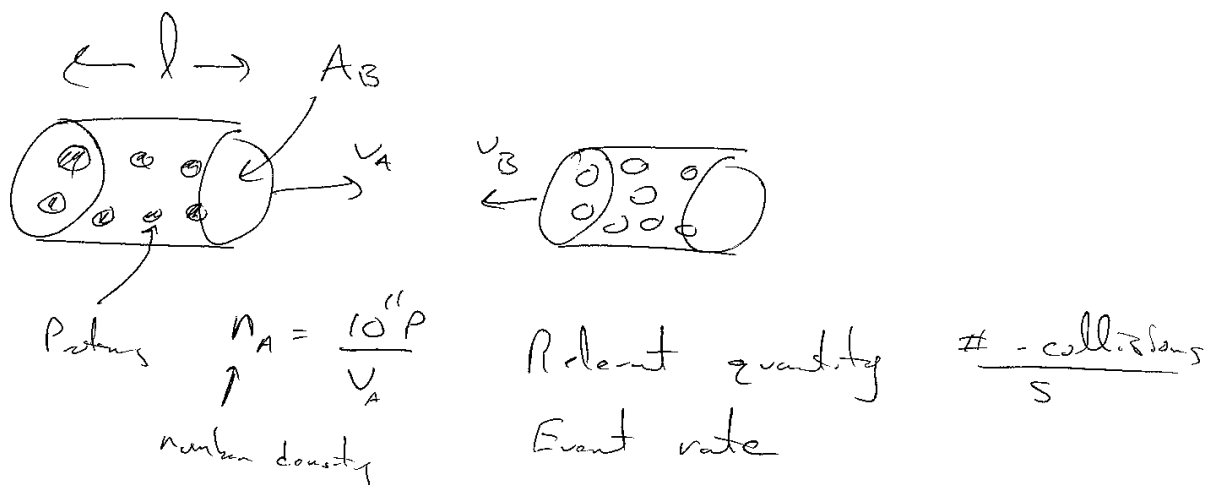

- nanobarns ( $\sim 10^{-9}$  b)
- picobarns ( $\sim 10^{-12}$  b)
- femptobarns ( $\sim 10^{-15}$  b)

One of the few units in particles physics not in natural units.

Now, colliding protons is hard.

- In order to get two protons to interact need to get them with an  $fm \sim 10^{-15}m$  of each other.
- To get around this, we collide bunches of protons

Bunch is  $\sim 10^{11}$  protons

Think about a slice of bunch “B”.

The number of protons in bunch A that it sees per time is

$$\frac{N_A}{t} = n_A \cdot \underbrace{A_B \cdot |v_A - v_B|}_{\substack{\text{Volume} \\ \text{time}} \text{ of A that passes through B}}$$

Now the number of protons in B that could interact is

$$N_B^{\text{eff}} = n_B \cdot \underbrace{l \cdot \sigma}_{\text{Volume of the protons}}$$

⇒

$$\frac{\text{Events}}{\text{Time}} = \frac{N_A N_B^{\text{eff}}}{t} = \underbrace{n_A n_B A l |v_A - v_B|}_{\text{flux factor we thought about before}} \sigma$$

- Flux factor depends on how the LHC was build
- $\sigma$  is an intrinsic physical observable

Integrated Luminosity  $L = \int dt L$

Number of events is given by  $N = L \times \sigma$

**Q: What is the flux factor at the LHC ?**

Flux Factor also called  $L$  “instantaneous luminosity” or just “luminosity”

$$L = n_A n_B A l |v_A - v_B| = \frac{N_A N_B |v_A - v_B|}{\underbrace{Vol}_{\text{Vol. of bunch} = A_B \times l}}$$

Now  $\sigma$  is fixed, so to maximize number of events collected, need to maximize  $L$

- $N_A = N_B = N = 10^{11}$  (fixed)
- $|v_A - v_B| = 2c$  can get much higher!
- $Vol \sim A_B \cdot l$

At the LHC, acceleration is done with radio-frequency EM feild that fixes  $l$  (Protons ride in the troughs of this feild) The wavelength of this feild sets  $l \sim \frac{c}{2 \times 400 \text{ MHz}} \sim \frac{3}{4} m$  The one handle we have is  $A_B$ , focusing magnets (quadruples) act like a lens near the collision points to squeeze the beam. So far focusing magnets have achieved squeezing down to the radii of  $10 \mu m$ ! Width of a human hair.

$$A_B \sim 10^{-10} m^2$$

$\Rightarrow$

$$L = 2c \frac{N^2}{l A} \sim 10^{-36} cm^{-2} s^{-1}$$
